Harnessing the power of deep learning leads to better predictions of patient admissions and flow in emergency departments.

Using a [deep-learning](#) model designed for [high-dimensional data](#), KAUST researchers have shown that it is possible to predict emergency

department overcrowding from complex hospital records. This application of the "Variational AutoEncoder" deep-[learning model](#) is an example of how [machine learning](#) can be used to interpret and extract meaning from difficult data sets that are too voluminous or complex for humans to decipher.

Machine learning is an important aspect of artificial intelligence (AI) that involves training an AI model using [training data](#). An AI model could learn, for example, to recognize images of the number three by training it using a data set containing thousands of versions of handwritten numerals. A simple neural network model—comprising interconnected "neurons" that take an input, apply a rule and produce an output—becomes increasingly accurate as it is exposed to more training data and the rules on each neuron are refined.

By adding hidden intermediate layers of neurons into these networks, however, the model can be prompted to self-learn the relationships in the input data without the rules being specified in advance. Such models, known as deep-learning models, are extremely powerful because they allow us, for the first time, to interpret data that has previously been too large, heterogeneous or multiparametered to meaningfully analyze any other way.

"Deep learning has emerged as a promising line of research in modeling and forecasting, in both academia and industry," says Fouzi Harrou, a research scientist at KAUST. "These models can automatically extract information from voluminous datasets with limited human instruction, such as implicit relationships between variables, complicated pattern recognition and descriptions of dependencies in time series data."

Harrou, with statistician Ying Sun from KAUST and collaborators from France and Algeria, applied a particularly promising deep-learning-based [model](#) called a Variational AutoEncoder (VAE) to the problem of

predicting patient admissions and flow through an emergency department in a pediatric hospital.

"A particularly attractive feature of VAEs is their ability to compress high-dimensional, or many-parameter, data into a lower-dimensional representation, which enables flexible generation of quantitative comparisons," says Harrou. The results demonstrated that the VAE approach performs better than other models, providing a range of insights, such as peak patient admission days and causative relationships.

"Accurate forecasting of patient arrivals is essential for [emergency department](#) managers to reduce patient waiting time and length of stay," says Harrou. "Our results clearly show the promising performance of deep-learning models for such applications, and we are now working to extend the approach to COVID-19 case forecasting."
